PHYSICAL REVIEW E 00, 002400 (2018)

Theory of time-averaged neutral dynamics with environmental stochasticity

Matan Danino and Nadav M. Shnerb

Department of Physics, Bar-Ilan University, Ramat-Gan 52900, Israel

(Received 30 November 2017; published xxxxx)

Competition is the main driver of population dynamics, which shapes the genetic composition of populations and the assembly of ecological communities. Neutral models assume that all the individuals are equivalent and that the dynamics is governed by demographic (shot) noise, with a steady state species abundance distribution (SAD) that reflects a mutation-extinction equilibrium. Recently, many empirical and theoretical studies emphasized the importance of environmental variations that affect coherently the relative fitness of entire populations. Here we consider two generic time-averaged neutral models; in both the relative fitness of each species fluctuates independently in time but its mean is zero. The first (model A) describes a system with local competition and linear fitness dependence of the birth-death rates, while in the second (model B) the competition is global and the fitness dependence is nonlinear. Due to this nonlinearity, model B admits a noise-induced stabilization mechanism that facilitates the invasion of new mutants. A self-consistent mean-field approach is used to reduce the multispecies problem to two-species dynamics, and the large-N asymptotics of the emerging set of Fokker-Planck equations is presented and solved. Our analytic expressions are shown to fit the SADs obtained from extensive Monte Carlo simulations and from numerical solutions of the corresponding master equations.

DOI: 10.1103/PhysRevE.00.002400 20

I. INTRODUCTION

Neutral models play a central role in the theoretical analysis 22 of population genetics and community ecology [1-3]. These 23 models neglect the details of interspecific interactions and 24 emphasize the role of stochastic processes as key drivers 25 of abundance variation and species diversity. Deterministic 26 factors (like selection, niche partitioning, and species specific 27 interactions) are not included in the model. Instead, one consid-28 ers a (usually, zero sum) competition between types (species, 29 strains, alleles, etc.) where all the individuals are functionally 30 equivalent ("neutral"). The structure of a community, i.e., the 31 commonness or rarity of different species, reflects the inherent 32 stochasticity of the underlying birth-death process, while the 33 corresponding birth-death rates are species independent and 34 are fixed in time. 35

A two-species competition of this kind is described by 36 the classical voter model [4] that leads, inevitably, to the 37 extinction of one of the species and to fixation by the other. 38 When the model allows for mutation or speciation events 39 the system may reach a steady state that reflects the balance 40 between mutations and extinctions. Quantities like the species 41 abundance distribution (SAD, also known as the site frequency 42 spectrum) and the mean species richness (SR) may then be cal-43 culated as a function of the model parameters [3,5]. The ability 44 of these SADs to account for empirically observed species 45 abundance distributions in many high-diversity assemblages 46 [6-8] is considered as the main success of the neutral model 47 of biodiversity. 48

Despite their great influence, some aspects of the traditional 49 neutral models are problematic. In particular, these models 50 assume that the dynamics is driven by a stationary birth-death 51 process. Under this assumption, variations in abundance of 52 a species reflect the cumulative effect of the uncorrelated 53

reproductive success of all its individuals. In such a binomial 54 process both the per-generation population variance and the time to extinction (in generations) scale linearly with the 56 population size. In contrast, many empirical analyses show that 57 the magnitude of temporal abundance variations is much higher 58 [9–14], that the scaling of population variance with population 59 size is superlinear [12,15], and that the rate of changes in $_{60}$ species composition is much faster than the predictions of the 61 neutral model [16,17]. 62

The simplest solution to that problem is environmental 63 stochasticity [18] (also known as fluctuating selection [19,20], 64 temporal niches, etc.): a time-varying environment may alter 65 the demographic parameters (such as growth and mortality 66 rates) and the competitive ability of an entire population, so 67 the reproductive success (say, the average number of offspring) 68 of all the conspecific individuals increases or decreases in a 69 correlated manner. Accordingly, population variance scales 70 with n^2 , where *n* is the population size. The stochastic process 71 is no longer stationary, and at any given time some species are 72 superior and others are inferior. The model may still be consid-73 ered as neutral if the time-averaged fitnesses of all species are 74 equal (time-averaged neutrality [17]). Numerical and empirical analyses suggest that time-averaged neutral models of this type may explain both static and dynamic patterns in ecological 77 communities [17,21]. These observations raise the need for an 78 analytic solution for time-averaged neutral models.

A few versions of the two-species time-averaged neutral 80 model were considered recently (sometimes in the context 81 of the speed of evolution [22,23]), and quantities like the 82 chance of fixation and the time to fixation were calculated 83 [24–29]. Other works dealt with the dynamics of a single ⁸⁴ species under environmental variability, trying to infer the 85 SAD of the corresponding multispecies neutral model from 86 the results [30-32]. Here we present a solution for the species ⁸⁷

TABLE I. Glossary. Term Description Ν Number of individuals in the community. The strength of demographic noise scales like 1/N. ν The chance of mutation or speciation (per birth). $\theta \equiv N v$ The fundamental biodiversity number. Mean number of mutations per generation. δ Correlation time of the environment, measured in generations. The amplitude of the fitness fluctuations. γ $\gamma^2 \delta/2$, the strength of environmental stochasticity. g The ratio between environmental stochasticity and demographic noise. $G \equiv Ng$ $\nu/g = \theta/G$ The ratio between mutation load and environmental stochasticity.

⁸⁸ abundance distribution in a multispecies time-averaged neutral
 ⁸⁹ model, where the process of species extinction is compensated

⁸⁹ model, where the process of species extinction is compensated ⁹⁰ by the introduction of different types via mutation or spe-⁹¹ ciation events. Our results are given in terms of the chance ⁹² for mutation, the strength of demographic noise, and the ⁹³ amplitude of environmental variations; the relevant definitions ⁹⁴ are summarized in Table I.

Technically speaking, neutral models are easier to solve 95 since the multispecies problem may be reduced to a set of 96 (identical) single species problems [33]. The abundance of 97 focal species n and the size of the community N fully 98 determine the transition rates of this focal species, since 99 demographic equivalence implies that the partitioning of the 100 N - n individuals among all other species is irrelevant. This 101 feature is lost when environmental variations are taken into 102 account, as the instantaneous fitness of all other individuals 103 does affect the focal species. We will show that, in high 104 diversity assemblages, this obstacle may be overcome using 105 an effective medium theory that becomes even simpler in the 106 large N limit. 107

To pave the way for this analysis, we will consider first 108 a two-type, one-way mutation model with environmental 109 stochasticity. In this model the state (abundance and fitness) 110 of the focal species unambiguously determines the state of the 111 whole system, so the analysis is relatively easy. Then we will 112 show that the full, multispecies model may be reduced (with 113 appropriate modifications) to the two-species case and, using 114 this feature, we obtain the required SADs. 115

To facilitate the discussion, we introduce three appendixes 116 in which technicalities are introduced and discussed. Ap-117 pendix A explains, using a simple example, the transition from 118 the master equation to the Fokker-Planck equation with a par-119 ticular emphasis on the boundary conditions. The correspond-120 ing calculations for the two-species, one-sided mutation case 121 are presented in Appendix B, and the relevant modifications 122 that allow us to solve the time-averaged neutral model are 123 discussed in Appendix C. 124

II. MODELS A AND B: ENVIRONMENTAL STOCHASTICITY AND NOISE INDUCED STABILIZATION

¹²⁷ In this section we would like to provide a few basic ¹²⁸ insights regarding the effect of environmental variations, and ¹²⁹ in particular to make a distinction between microscopic models ¹³⁰ that lead to noise-induced stability and those that do not ¹³¹ support this feature. Our two examples here involve global ¹³² and local competition; we first present these models with pure demographic noise, where they lead to the same outcome, ¹³³ then we will explain their different behavior in fluctuating ¹³⁴ environment. ¹³⁵

As an example of local interactions (model A), one may 136 imagine two populations that live together on, say, an island. 137 Individuals are wandering around, looking for food, mates, or 138 territory. An encounter between two individuals may lead to a 139 struggle in which only one of them wins the desired goods and increases its chance to survive and to reproduce. In a zero-sum 141 game of this kind two individuals are chosen at random from the entire community for a duel; the loser dies and the winner 143 produces a single offspring. If one considers a two-species 144 community of size N, where the fraction of one species is 145 x = n/N, the chance for an interspecific duel is 2x(1 - x). In a 146 neutral model without environmental variations all individuals 147 have equal fitness all the time, so the chance to win a duel is 148 always 1/2. Accordingly, the chance of a population to grow 149 or to decrease by one individual after a single elementary event 150 (a duel) is equal, x(1 - x). 151

To present a model with global competition (model B), let 152 us consider a forest. Adult trees spread seeds all around and 153 we assume that the dispersal length is much larger than the 154 size of the forest, so the composition of the seed bank at each 155 location reflects the abundance of the corresponding species in 156 the forest. When an adult tree dies it leaves a gap and one local 157 seed is chosen to capture it. If the model is neutral the chance 158 of each species to recruit the gap is proportional to its relative 159 abundance. Hence, the abundance of x will grow by one tree 160 with probability x(1 - x) [an adult tree from another species 161 has been chosen to die with probability (1 - x) and the focal 162 species won the gap with probability x] and will shrink by one 163 tree with the same probability. 164

Accordingly, when the environment is fixed and the dynamics is purely neutral, the local competition model (A) and the global competition model (B) are translated to the same stochastic process (the voter model) and lead to the same dynamics. However, this feature is lost when environmental fluctuations do affect the relative fitness of different species, even if the averaged fitness differences vanish.

To model environmental stochasticity we begin with a twospecies game, and later on we will extend the definition to the general case. Focusing on a specific species with relative abundance x, in model A the chance of an interspecific duel is 2x(1 - x). We will define the fitness of this species (with respect to its enemy) via the chance to win such a duel, 177

$$P_{\rm win} = \frac{1}{2} + \frac{\gamma(t)}{4},$$
 (1)

THEORY OF TIME-AVERAGED NEUTRAL DYNAMICS WITH

where $\gamma(t)$ measures its relative (log) fitness. The focal species mean population satisfies (time is measured in generations, *N* elementary events in each generation),

$$\dot{x} = \gamma x (1 - x), \tag{2}$$

¹⁸¹ or $\dot{z} = \gamma z$, where $z \equiv x/(1 - x)$. Accordingly, if γ is fixed in ¹⁸² time the focal species abundance grows (when γ is positive) or ¹⁸³ decays (for $\gamma < 0$) and the focal species reaches fixation (z >¹⁸⁴ 1 - 1/N) or extinction (z < 1/N) on $\mathcal{O}(\ln N)$ timescales. Our ¹⁸⁵ interest here is in a time-averaged neutral model where $\gamma(t)$ ¹⁸⁶ has zero mean. In that case $\ln(z)$ performs a simple unbiased ¹⁸⁷ random walk without any stabilizing force.

In model B the role of environmental variations is not so 188 simple. If the fitness affects the chance of recruitment but death 189 occurs randomly, the chance of the focal species to increase 190 its abundance is equal to the chance that a tree from another 191 species dies, 1 - x, times the chance of the focal species to 192 win the empty slot, which is defined to be the ratio between 193 194 the fitness of the local species and the average fitness of the 195 community,

$$\frac{xe^{\gamma}}{(1-x)+xe^{\gamma}}.$$
(3)

¹⁹⁶ The focal species shrinks if one of its individuals was chosen ¹⁹⁷ to die (with probability x) and the other species wins the com-¹⁹⁸ petition with probability $(1 - x)/(1 - x + xe^{\gamma})$. Accordingly, ¹⁹⁹ x satisfies

$$\frac{dx}{dt} = \frac{x(1-x)e^{\gamma}}{1-x+xe^{\gamma}} - \frac{x(1-x)}{1-x+xe^{\gamma}}$$
$$\approx \gamma x(1-x) + \frac{\gamma^2}{2} x(1-x)(1/2-x), \qquad (4)$$

where the last term comes from a second order expansion 200 in γ . Unlike model A, here the nonlinear dependence of the 201 chance to win on γ leads to a second, $\mathcal{O}(\gamma^2)$ term, that by itself 202 tends to stabilize the coexistence point at x = 1/2. Of course 203 this term is much smaller than the first, $\mathcal{O}(\gamma)$ term, so under 204 fixed environmental conditions the focal species still shrinks 205 or grows exponentially. However, when $\gamma(t)$ fluctuates around 206 zero the $\mathcal{O}(\gamma)$ term averages out while the $\mathcal{O}(\gamma^2)$ terms add 207 up, so (at least when the rate of variations is fast enough) the 208 stochasticity tends to stabilize the coexistence point. 209

The difference between model A and model B is most 210 evident when the environmental fluctuations are extremely 211 rapid, e.g., when γ is picked at random after each elementary 212 (birth-death) event. Model A reduces, in this case, to its purely 213 demographic limit: instead of choosing the winner by a single 214 toss of a coin one first picks the weather and then the winner, 215 but the end result is a chance of 1/2 to win any elementary 216 competition. In contrast, in model B the stabilizing effect of 217 the environment reaches its maximum strength in this rapid 218 fluctuations limit where the $\mathcal{O}(\gamma)$ terms cancel each other more 219 220 efficiently.

The stabilizing effect of environmental variations in models with nonlinear fitness dependence (like our model B) was pointed out by Chesson and co-workers a while ago [34,35]. Technically, model B considered here is very close to Chesson-Warner lottery game. However, as discussed in [25], the lottery game has no demographic noise, so it does not allow for extinction events and one cannot analyze the properties of a 230

231

232

237

community in which the biodiversity reflects an extinctionspeciation equilibrium. 229

III. AN INDIVIDUAL-BASED TWO-TYPE MODEL WITH ENVIRONMENTAL STOCHASTICITY AND ONE-WAY MUTATION

As explained above we shall start our analysis, in this ²³³ section, with a two-species game, and then (in Sec. IV) extend ²³⁴ the treatment to the full problem. In these two sections we ²³⁵ begin with model A and then consider model B. ²³⁶

A. Model A

Let us consider a system of N individuals with two species ²³⁸ (types), A and B. As in [36] (p. 208) no mutation of B to A is ²³⁹ allowed, while an offspring of type A may mutate to become ²⁴⁰ a B type. ²⁴¹

In each elementary event two individuals are picked at ²⁴² random; the winner reproduces and the loser dies. If a *B* type ²⁴³ wins, the offspring is also a *B*. If an *A* wins, the offspring is ²⁴⁴ an *A* with probability $1 - \nu$ and mutates to be a *B*-type with ²⁴⁵ probability ν . ²⁴⁶

Accordingly, in a system of *N* individuals with *n A* types ²⁴⁷ and N - n *B* types, the only absorbing state is n = 0. In this ²⁴⁸ section we assume that, very rarely, a new *A*-type individual ²⁴⁹ arrives (say, as an immigrant) and then the game is played again ²⁵⁰ until the *A* species goes extinct (this happens before the next ²⁵¹ immigration event). Our aim is to calculate P_n , the probability ²⁵² to find the system with *n A* types, *conditioned* on the existence ²⁵³ of *A* in the system (i.e., not including the periods between ²⁵⁴ extinction and recolonization events). ²⁵⁵

As explained, this process takes place via a series of duels. ²⁵⁶ In case of an interspecific duel A wins with probability P_{win} ²⁵⁷ (to be defined below) and B wins with probability $1 - P_{win}$. ²⁵⁸ The possible outcomes of all kinds of duels are summarized ²⁵⁹ by (here the expressions above the arrows are probabilities, not ²⁶⁰ rates) ²⁶¹

$$B + B \xrightarrow{1} 2B \quad A + A \xrightarrow{1-\nu} 2A \quad A + A \xrightarrow{\nu} A + B$$
$$A + B \xrightarrow{1-P_{\text{win}}} 2B \quad A + B \xrightarrow{P_{\text{win}}(1-\nu)} 2A \quad A + B \xrightarrow{\nu P_{\text{win}}} A + B.$$
(5)

To fully characterized the process, $P_{\rm win}$ should be specified. ²⁶² We define $P_{\rm win}$ via ²⁶³

$$P_{\rm win} = \frac{1}{2} + \frac{s_A - s_B}{4},\tag{6}$$

where s_A (s_B) is the logarithmic fitness of the A (B) type. ²⁶⁴ Without loss of generality we can set $s_B = 0$. Under environmental variations s_A (hence P_{win}) is time dependent, but to ²⁶⁶ keep time-average neutrality its mean has to be zero. Clearly, ²⁶⁷ the main characteristics of such environmental fluctuations are ²⁶⁸ their amplitude and their correlation time. Here we assume a ²⁶⁹ dichotomous (telegraphic) noise such that $s_A = \pm \gamma$, so half of ²⁷⁰ the time $P_{win} = 1/2 + \gamma/4$ (the plus state of the environment) ²⁷¹ and half of the time $P_{win} = 1/2 - \gamma/4$ (the minus state). Both ²⁷² white Gaussian noise and white Poisson noise can be recovered ²⁷³ from the dichotomous noise by taking suitable limits [37], so ²⁷⁴ the results obtained here are quite generic. ²⁷⁵ Time is measured in units of generations, where a generation is defined as N elementary duels. After each elementary duel the environment switches (from $\pm \gamma$ to $\mp \gamma$) with probability $1/(N\delta)$, so the sojourn times of the environment (measured in generations) are geometrically distributed with mean δ .

At this point the model is fully specified. A full list of 281 the transition probabilities is given in Appendix B, Eq. (B2). 282 Using that, one may write down the corresponding set of 283 master equations (B1). In Appendix B we show how to derive, 284 from this exact master equation, an effective Fokker-Planck 285 equation for P(x); the chance (averaged over time, including 286 plus and minus periods) to find the system with $n \equiv Nx A$ -type 287 individuals, satisfies 288

$$\{x(1-x)[1+Gx(1-x)]P(x)\}'' - \{[Gx(1-x)(1-2x)-\theta x]P(x)\}' = 0.$$
 (7)

Here tags are derivatives with respect to *x* and $G \equiv N\delta\gamma^2/2$ is the ratio between the effective strength of the environmental stochasticity, $g = \gamma^2 \delta/2$, and 1/N, the strength of the demographic noise. The fundamental biodiversity number $\theta = N\nu$ is a measure of the population mutation rate (mutation load per generation).

Solving for P(x) with the appropriate boundary conditions (see Appendixes A and B, where we explain this subtle issue), one obtains

$$P(x) = C \frac{(1-x)^{\theta}}{x(1-x)[1+Gx(1-x)]^{\theta/2}} \\ \times \left[\frac{1-(1-2x)\sqrt{\frac{G}{4+G}}}{1+(1-2x)\sqrt{\frac{G}{4+G}}}\right]^{(\theta/2)\sqrt{G/(4+G)}}, \quad (8)$$

where *C* is a normalization factor. To provide a background for later discussions, let us consider a few features of the solution (8).

(1) When $G \rightarrow 0$ (no environmental stochasticity) we have a model with mutations and demographic noise. In that case, P(x) obtained from our two-species model is simply

$$P(x) = C \frac{(1-x)^{\theta-1}}{x},$$
(9)

i.e., the Fisher log series that converges to $e^{-\theta x}/x$ when $\theta \gg$ 304 1. In this case the two-species model yields the SAD of the 305 neutral model, since there is no real difference between the 306 two. Every species in the neutral model emerges via mutation 307 or speciation and goes extinct because of demographic noise, 308 so the average over colonization-extinction periods that yields 309 P(x) is the same as the average over different species that yields 310 the SAD of the neutral model. As we shall see below, when 311 environmental stochasticity kicks in, P(x) of the two-species 312 model differs from the SAD of the neutral model. 313

³¹⁴ When $\theta \ll 1$ the expression for P(x) in Eq. (9) reduces to ³¹⁵ $[x(1-x)]^{-1}$, since in that case the system spends most of its ³¹⁶ time close to the fixation or extinction points in a symmetric ³¹⁷ manner.

(2) For strong environmental stochasticity, i.e., when $G \gg$ 319 1, one may use the approximation $\sqrt{G/(G+4)} \approx 1 - 2/G$. When this expression is plugged into Eq. (8) and constants are ³²⁰ absorbed into the normalization factor one obtains ³²¹

$$P(x) = C(1-x)^{\nu/g-1} \left(\frac{(1+Gx)(1-x)}{1+Gx(1-x)}\right)^{\theta/2} \frac{(1+Gx)^{-\nu/g}}{x}.$$
(10)

When all parameters are kept fixed and x decreases such that $_{322}$ $Gx \ll 1$ and $\theta x \ll 1$ (which implies, of course, also $x \ll 1$), $_{323}$ the dynamics is purely demographic and Eq. (10) reduces to $_{324}$

$$P(x) \sim \frac{1}{x}.\tag{11}$$

On the contrary, in the region where the demographic noise in $_{325}$ negligible, $Gx \gg 1$, $_{326}$

$$P(x) \sim \frac{(1-x)^{\nu/g-1}}{x^{\nu/g+1}} \exp\left(-\frac{\theta x/2}{1+Gx(1-x)}\right).$$
 (12)

(i) When $\nu > 2g$, the exponent in (12) truncates P(x) at 327

$$x_c = \frac{1}{N(\nu/2 - g)}.$$
 (13)

In the large *N* limit $x_c \ll 1$ so $(1 - x)^{\nu/g-1} \approx 1$. Accordingly, ³²⁸ *P*(*x*) looks like 1/x for $x \ll 1/G$, like $x^{-1-\nu/g}$ in the narrow ³²⁹ region $1/G \ll x \ll 1/(\theta/2 - G)$, and decays to negligible ³³⁰ values above this point. The intermediate power-law regime ³³¹ disappears when $\nu > 4g$, where *P*(*x*) takes the general form ³³² of the Fisher log series with an effective mutation rate which ³³³ is half of the bare mutation rate, plus some modifications due ³⁴⁴ to *G* in the tail of the distribution. ³³⁵

(ii) When v = 2g the exponential term in Eq. (12) still provides a cutoff, now at $x_c \sim 1/\sqrt{G}$. Since x_c is still microscopic in the large N limit, the intermediate power law x^{-3} is valid in the region $1/G \ll x \ll 1/\sqrt{G}$.

(iii) If $\nu < 2g$, the exponential cutoff point becomes N 340 independent, 341

$$x_c = 1 - \frac{\nu}{2g},\tag{14}$$

342

354

so,

$$P(x) \sim \frac{(1-x)^{\nu/g-1}}{x^{\nu/g+1}} e^{-\nu/2g(1-x)}.$$
 (15)

Below x_c , the behavior is determined by the pre-exponential 343 factor. If g < v < 2g, this factor decays monotonously with x, 344 so one observes two power laws with an Arrhenius truncation 345 above x_c . In the region v < g the prefactor grows with x above 346 $x^* = 1/2 + v/(2g)$. When $x^* < x_c$, i.e., v < g/2, P(x) admits 347 an observable peak at finite x, as demonstrated in Fig. 1(b). 348

The adequacy of Eq. (8) and the different behaviors of 349 P(x) are demonstrated in Fig. 1. The analytic predictions are 350 shown to fit the outcomes of Monte Carlo simulations and the 351 numerical solutions of the master equation. As expected, when 352 g > v a peak appears close to x = 1. 353

B. Model B

In model B, each elementary step begins with the death ³⁵⁵ of a randomly chosen individual, so death probability is ³⁵⁶ fitness independent. In our one-sided mutation game, with ³⁵⁷

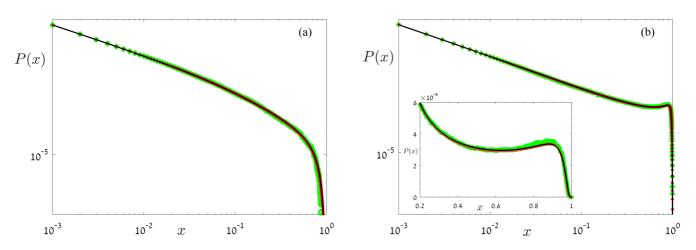

FIG. 1. P(x), the chance of finding the A-type at relative abundance x, is plotted for a two competing species system with one-sided mutation, environmental stochasticity, and demographic noise. In both figures N = 1000, v = 0.01, and the main panels are plotted using a double logarithmic scale. Results shown include those obtained from a Monte Carlo simulation (green circles), numeric solutions for the steady state of the master equations (B1)–(B3) (red diamonds), and the analytic prediction of Eq. (8) (black line). In panel (a) the results are depicted for $\delta = 0.5$ and $\gamma = 0.2$, such that v = g. In panel (b) $\delta = 1.25$ and $\gamma = 0.4$ so v = 0.1g. As discussed in the main text, when v < g/2 there is a peak at high values of x. To emphasize this peak we have added an inset where the same results are shown using a linear scale. The fit between the three curves is quite good.

³⁵⁸ probability ν the gap is recruited by a *B* type individual. ³⁵⁹ With probability $1 - \nu$ the chance of each species to capture ³⁶⁰ the vacancy is proportional to its abundance, weighted by its ³⁶¹ fitness. Accordingly, if the relative logarithmic fitness of *A* type ³⁶² is γ and its fraction is *x*, its chance to increase its population ³⁶³ by 1 comes from events where a *B* individual was chosen to ³⁶⁴ die (with probability 1 - x) and no mutation happens, so the transition probabilities are

$$W_{n \to n+1} = (1 - \nu) \frac{(1 - x)xe^{\gamma}}{1 - x + xe^{\gamma}},$$

$$W_{n \to n-1} = x \left(\nu + (1 - \nu) \frac{(1 - x)}{1 - x + xe^{\gamma}} \right).$$
 (16)

365

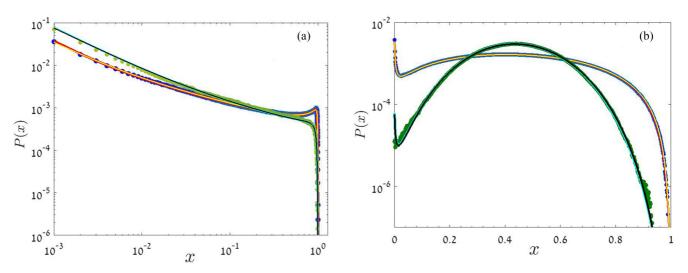

FIG. 2. $P_{\text{modelB}}(x)$, the chance of finding the *A* type at relative abundance *x*, is plotted for a system with two competing species with one-sided mutation, environmental stochasticity, and demographic noise. In both figures N = 1000, v = 0.005. Results shown include those obtained from a Monte Carlo simulation (filled circles), numeric solution for the steady state of the master equations, and the analytic prediction of Eq. (18) (lines with different colors). In panel (a) (plotted using a double logarithmic scale) the results are depicted for large value of δ , $\delta = 2$, so the outcomes imitate those obtained for model A, in particular the two power laws when $\gamma = 0.2$ (green circles) and the peak close to x = 1 when $\gamma = 0.4$ (blue circles). In panel (b) (where the scale we have used is semilogarithmic) $\gamma = 0.4$ while $\delta = 0.4$ for the blue circles and $\delta = 0.1$ for the greens. Since δ is small, the peak at x = 1/2 is pronounced, and it becomes even steeper as δ decreases. In all these graphs the fits are good, and one can hardly distinguish between the numeric solution for the steady state and the analytic expression (18). Here, and in all other figures, the marker sizes were chosen to allow one to distinguish between the three data sets, but the actual width of the lines is smaller. We did not track the standard deviation associated with the outcomes of our Monte Carlo simulations, but the almost perfect agreement between the lines obtained using three different techniques implies that the corresponding error bars are tiny.

³⁶⁶ Under dichotomous environmental stochasticity after each step ³⁶⁷ the system switches from $\pm \gamma$ to $\mp \gamma$ with probability $1/(N\delta)$. ³⁶⁸ Implementing the same method used for model A, one finds

Implementing the same method used for model A, one the corresponding Fokker-Plank equation,

$$\{x(1-x)[1+Gx(1-x)]P(x)\}'' - \{[(G\eta x(1-x)(1-2x) - \theta x]P(x)]' = 0, \quad (17)$$

where $\eta \equiv 1 + 1/\delta$. The only difference between this Fokker-370 Planck equation and the equation for model A [Eq. (7)] is the in-371 nocent looking factor η . However, this may lead to a substantial 372 modification of the results. In model A, the deterministic bias 373 towards x = 1/2, represented by the Gx(1-x)(1-2x) in the 374 convection term, is balanced by the decrease in the diffusion 375 rate close to the edges, related to the factor $Gx^2(1-x)^2$ in 376 the diffusion term, and the two phenomena cancel each other 377 exactly in the steady state [30]. Since $\eta > 1$, the attraction 378 towards 1/2 is dominant in model B, hence the steady-state 379 probability may have a peak at a finite value of x. 380

³⁸¹ The steady state of model B turns out to be

$$P(x) = C \frac{(1-x)^{\theta}}{x(1-x)[1+Gx(1-x)]^{-1/\delta+\theta/2}} \\ \times \left[\frac{1-(1-2x)\sqrt{\frac{G}{4+G}}}{1+(1-2x)\sqrt{\frac{G}{4+G}}}\right]^{(\theta/2)\sqrt{G/(4+G)}} \\ = [1+Gx(1-x)]^{1/\delta} P_{\text{Model}A}.$$
(18)

6

390

391

Clearly, the extra term has a maximum at x = 1/2 and the peak becomes more pronounced when δ decreases, as expected.

Therefore, model B is richer than model A: for $\delta \gg 1$, P(x)in model B may yield the same behaviors described above, such as a truncated power law or a peak close to x = 1. However, when $\delta \ll 1$ the stabilizing force is strong and the probability develops a peak close to x = 1/2. These behaviors are demonstrated in Fig. 2.

IV. A MULTISPECIES, TIME-AVERAGED NEUTRAL MODEL

Having solved the problem of a two-species system with environmental stochasticity and one-sided mutation, we return to the main goal of this paper: the attempt to find the SAD of a neutral model with both demographic and environmental stochasticity. In this model the system may support many species, and each of these species is characterized by its abundance n and by its instantaneous fitness.

Without environmental noise the dynamics of every focal 399 species in a neutral system is identical to the dynamics of type 400 A in the two-species one-sided mutation model considered in 401 the previous section. Accordingly, as demonstrated in the last 402 section, in that case the function P(x) of the two-species model 403 is proportional, up to a normalization constant, to the SAD 404 of the multispecies neutral model [defined also as P(x), but 405 now it is the probability that a randomly picked species has 406 abundance x]. When the environmental variations change the 407 relative fitness of different species this is not the case anymore. 408 In this section we develop an effective field theory that allows 409 us to map the neutral model to a (slightly modified) two-species 410

414

system. Once this goal is achieved, we can solve for the SAD 411 using the techniques presented above. Again, we begin with a 412 discussion of model A, then we consider model B. 413

A. Model A

As before, in each elementary step two individuals are 415 picked randomly for a duel, and the winner is determined 416 with probability that depends on their relative fitness. The 417 offspring takes the species identity of its parent with probability 418 1 - v and becomes the originator of a new species with 419 probability v. Unlike the two-species model, here there are 420 no recurrent mutations—an offspring cannot mutate into an 421 existing type (an infinite allele model). As a result, the structure 422 of the community reflects the balance between mutations and 423 extinction events. 424

The environmental noise is again dichotomous: there are 425 two fitness state, $\pm \gamma$, and the fitness of every species jumps 426 randomly between these two states, such that the sojourn times 427 are distributed geometrically with mean of δ generations. The 428 states of different species are not correlated, and the fitness of 429 an originator of a species is chosen at random upon its birth. Accordingly, in this time-averaged neutral model there are two types of duels: the two randomly picked individuals may have 432 the same fitness (either plus or minus), in which case the chance 433 of each of them to win the duel is 1/2, or they may have 434 different fitnesses, in which case the corresponding chances 435 will be $1/2 \pm \gamma/2$. Unlike the two-species model considered 436 in the last section, here two fighting individuals may have the 437 same fitness, so the $\gamma/4$ factor above has to be replaced by $\gamma/2$ 438 to keep the relationship between the environmental fluctuations 439 and the demographic noise fixed. The full specifications of the 440 model, including all the transition probabilities, are provided 441 in Appendix C. 442

Let us consider now the dynamics of a single (focal) species. ⁴⁴³ As opposed to the two-species system considered above, here ⁴⁴⁴ when an individual of the focal species is chosen for an ⁴⁴⁵ interspecific duel, the fitness of its rival is not specified uniquely ⁴⁴⁶ by the focal species fitness. For example, if the focal species ⁴⁴⁷ is in the plus state, it may compete with either an inferior or ⁴⁴⁸ an equal individual. Therefore, to analyze the dynamics of the ⁴⁴⁹ focal species we need an extra parameter f_+ , the chance that ⁴⁵⁰ its rival in an interspecific duel will be in the plus state. If f_+ ⁴⁵¹ is a constant (time, state, and abundance independent—see the ⁴⁵² discussion below), then the chance of a focal species individual ⁴⁵³ to win a duel, when the focal species is in the plus state, is ⁴⁵⁴

$$q = f_{+}\frac{1}{2} + (1 - f_{+})\left(\frac{1}{2} + \frac{\gamma}{2}\right) = \frac{1}{2} + \frac{\gamma}{2}(1 - f_{+}).$$
 (19)

When $f_+ = 1/2$ the dynamics reduces to the two-species 455 model considered above. 456

The introduction of the constant f_+ allows us to implement 457 the method presented in the last section to the dynamics 458 of a focal species in the time-averaged neutral model. In 459 Appendix C we show that, in this case, P(x) of an arbitrary 460 focal species (and hence the SAD of the model) satisfies 461

$$\{x(1-x)[1+Gx(1-x)]P(x)\}'' - \{[Gx(1-x)(1-2x) + N\gamma x(1-x)(1-2f_+) - \theta x]P\}' = 0.$$
 (20)

THEORY OF TIME-AVERAGED NEUTRAL DYNAMICS WITH ...

462 The solution of this equation is

$$P(x) = C \frac{(1-x)^{\theta}}{x(1-x)[1+Gx(1-x)]^{\theta/2}} \\ \times \left[\frac{1-(1-2x)\sqrt{\frac{G}{4+G}}}{1+(1-2x)\sqrt{\frac{G}{4+G}}}\right]^{(\theta/2-\zeta)\sqrt{G/(4+G)}}, \quad (21)$$

463 where

$$\zeta \equiv -\frac{2}{\gamma\delta}(1-2f_+).$$

In general f_+ may depend on the abundance of the focal 464 species. However, when the abundance of each species is only 465 a tiny fraction of N (which is the case when the system supports 466 many species, see below) one may expect it to be independent 467 of the details of the state of the system. Our numerics shows that 468 taking f_+ as a constant becomes a very good approximation 469 when N is large. In fact, f_+ turns out to be independent of the 470 abundance and the state (plus/minus) of the focal species, but 471 it fluctuates in time. Since the transition rates are linear in f_+ , 472 their average depends only on its mean, f_{\perp} . 473

Given that, we can obtain a closed form for the species abundance distribution by calculating \overline{f}_+ as a function of the system parameters. If all species are "microscopic" ($n \ll N$) \overline{f}_+ has to be, more or less, the fraction of individuals in the plus state, so it satisfies the self-consistency equation

$$\overline{f}_{+} = \frac{1}{\overline{x}} \int_{0}^{1} x P^{+}(x) \, dx.$$
(22)

⁴⁷⁹ $P^+(x)$ $[P^-(x)]$ is the probability that a randomly picked ⁴⁸⁰ species has abundance *x* and its fitness is $+\gamma$ $[-\gamma]$. The mean ⁴⁸¹ abundance of a species, $\overline{x} \equiv \int_0^1 x [P^+(x) + P^-(x)]$, is related ⁴⁸² to the total number of species (species richness) in the system, ⁴⁸³ SR, by $\overline{x} = 1/SR$.

⁴⁸⁴ This, plus the relationship we have derived from the master ⁴⁸⁵ equations in Appendix C [Eq. (C3)],

$$\frac{\gamma\delta}{2}[x(1-x)P]' = P^{-}(x) - P^{+}(x), \qquad (23)$$

⁴⁸⁶ leads, via integration by parts, to

$$\zeta = -\frac{2}{\gamma\delta}(1 - 2\overline{f}_{+}) = \frac{1}{\overline{x}} \int_{0}^{1} x(1 - x)P(x) = 1 - \frac{\overline{x^{2}}}{\overline{x}}.$$
(24)

Equations (21) and (24) provide a closed form for the species abundance distribution of the neutral model: the normalization constant *C* cancels out in (24), so one may use (24) to determine ζ which, in turn, specifies uniquely P(x). Moreover, if P(x) decays faster than x^{-2} , the quantity $\overline{x^2}/\overline{x}$ tends to zero as $N \to \infty$, so asymptotically

$$\zeta = -\frac{2}{\gamma\delta}(1 - 2\overline{f}_{+}) \to 1.$$
⁽²⁵⁾

⁴⁹³ The same result emerges from a simple argument about the ⁴⁹⁴ dynamics of f_+ : when all the species are microscopic, $\dot{f}_+ =$ ⁴⁹⁵ $2\gamma f_+(1 - f_+) - f_+/\delta + (1 - f_+)/\delta$, so (when $\gamma \delta \ll 1$) the ⁴⁹⁶ steady state is $f_+ \approx 1/2 + \gamma \delta/4$, in agreement with (25).

PHYSICAL REVIEW E 00, 002400 (2018)

Given that, one may easily recognize the qualitative features 497 of our main result, Eq. (21). As in the two-species case, when 498 all other parameters are kept fixed and $G \rightarrow 0$, the Fisher log- 499 series distribution is recovered. When *G* is large (21) reduces to 501

$$P(x) = \frac{C}{x(1-x)} \left[\frac{(1-x)(\frac{1}{G}+x)}{1+Gx(1-x)} \right]^{\theta/2} \left[\frac{(\frac{1}{G}+x)}{1-x} \right]^{-\zeta-\nu/g}.$$
(26)

There is, again, a demographic regime: as long as $Gx \ll 1$ 502 and $\theta x \ll 1$, $P(x) \sim 1/x$, as in Eq. (11) above. When $Gx \gg 1$ 503 one obtains 504

$$P(x) \sim \frac{(1-x)^{\nu/g+\zeta-1}}{x^{\nu/g+\zeta+1}} \exp\left(-\frac{\theta x/2}{1+Gx(1-x)}\right).$$
 (27)

This expression is very similar to (12), and the only modification is the replacement of ν/g by $\nu/g + \zeta$ in the preexponential factor. This implies that the general analysis presented in the discussion of the two-species case still holds: for $\nu > 2g$ the exponential truncation starts above x_c which is $\mathcal{O}(1/N)$ while for $\nu < 2g$, x_c is $\mathcal{O}(1)$. The only qualitative difference between the multispecies and the two-species case appears in the $\nu < g/2$ regime, where the pre-exponential function grows above $x^* = 1/2 + \nu/(2g) + \zeta/2$. One may see a peak at finite value of x only if $x^* < x_c$, a condition that translates to

$$\nu < \frac{g(1-\zeta)}{2}.\tag{28}$$

Therefore, when $N \to \infty$ and $\zeta \to 1$ there is no peak in the 516 species abundance distribution [see Fig. 3(b), in comparison 517 with Fig. 1(a)]. Since the decay is faster than $1/x^2$, the 518 assumption $\zeta \to 1$ is self-consistent. 519

In parallel with Fig. 1, Fig. 3 demonstrates the ability of 520 Eq. (21) to fit both the numerical solution of the master equation 521 and the outcomes of Monte Carlo (MC) simulations. Note 522 that, unlike the last section, here the agreement between the 523 MC simulations and the numerics of the master equations is 524 nontrivial, since the master equations were built for a single 525 species, assuming the ability to use an effective medium theory 526 with one parameter, f_+ . 527

B. Model B

Now let us present the analysis of the multispecies version 529 of model B presented above: a community with time-averaged 530 neutral dynamics, in which the competition is global and the 531 dependence of the transition rates on the fitness is nonlinear. 532

As before, we would like to reduce our analysis to a focal 533 species and to encapsulate the effect of all other individuals by 534 their average fitness *A*, defined as 535

$$A = f_{+}e^{2\gamma} + (1 - f_{+}), \qquad (29)$$

528

where, as before, f_+ measures the fraction (of all individuals that do not belong to the focal species) who are in the plus state. In parallel to our analysis of model A, we have multiplied the value of γ by a factor of 2, with respect to the two-species game, in order to keep the overall strength of environmental stochasticity g at $\gamma^2 \delta/2$. as we shall see below, here also the mean value of f_+ approaches $1/2 + \gamma \delta/4$.

PHYSICAL REVIEW E 00, 002400 (2018)

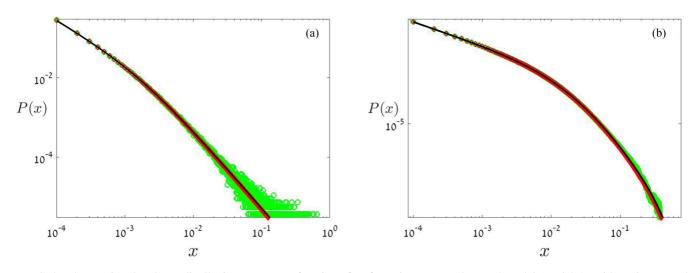

FIG. 3. The species abundance distribution, P(x) as a function of x, for a time-averaged neutral model (model A) with environmental stochasticity and demographic noise. In both figures $N = 10^4$ and v = 0.01, and the results are plotted using a double logarithmic scale. The outcomes of a Monte Carlo simulation (green circles), numeric solution for the steady state of the master equations (see Appendix C) (red diamonds) and the analytic predictions of Eq. (21) (black line) are compared, and the fit is very good. In panel (a) the results are depicted for $\delta = 0.5$ and $\gamma = 0.5$, such that v/g = 0.16. In panel (b) $\delta = 0.25$ and $\gamma = 0.2$ so v/g = 2. In both panels the small x behavior is $P \sim 1/x$, but in panel (a) this regime is very narrow since it requires $x \ll 1/G = 1.6 \times 10^{-3}$. The $Gx \gg 1$ behavior obeys a power law in panel (a), where the environmental stochasticity dominates (v/g < 1/2) and is dominated by an exponential decay in panel (b), where the mutation losses are stronger. In these parameters, N is not big enough to justify the use of the asymptotic value $\zeta = 1$. Instead, the value of \overline{f}_+ used in Eq. (21) was obtained by measuring the long-term average fraction of individuals in the plus state through the MC simulations.

Naively, one would like to define new transition probabilities for the focal species using *A*. Given the value of γ , these transition probabilities are

$$W_{n \to n+1} = (1 - \nu) \frac{(1 - x)xe^{2\gamma}}{(1 - x)A + xe^{2\gamma}},$$

$$W_{n \to n-1} = x \left(\nu + (1 - \nu) \frac{(1 - x)A}{(1 - x)A + xe^{2\gamma}}\right).$$
 (30)

⁵⁴⁶ From this point one may continue, as in model A, to derive the ⁵⁴⁷ two coupled master equations and the corresponding Fokker-⁵⁴⁸ Planck equations, from which an appropriate expression for ⁵⁴⁹ P(x) may be extracted.

When we did that, we discovered that the emerging for-550 mula for P(x) does not fit the outcome of our Monte Carlo 551 simulations. It turned out that the origin of the problem is the 552 f_+ fluctuations: since species flip continuously from the plus 553 to the minus state and vice versa, the number of species in 554 the plus state varies binomially. Accordingly, f_+ , which is the 555 number of species in the plus state times the average abundance 556 of such a species, fluctuates such that $f_+ = \overline{f}_+ + \delta f_+$, where 557 δf_+ is a random number taken, more or less, from a zero-mean 558 Gaussian distribution with width $\sigma \equiv \sqrt{\operatorname{Var}(f_+)}$. In general 559 σ $\rightarrow 0$ as $N \rightarrow \infty$, but to fit the results of our simulations 560 with finite N we had to use this parameter. In model A this 561 variance did not play any role, since the transition probabilities 562 are linear in f_+ so the average $W_{n\to n\pm 1}$ depends only of \overline{f}_+ . In 563 contrast, here the nonlinearity of the W's compels one to take 564 f_+ fluctuations into account. 565

Accordingly, we have implemented the procedure described above, replacing each of the W's of Eq. (30) by $\tilde{W} = (1/2)W(\bar{f}_+ + \sigma) + (1/2)W(\bar{f}_+ - \sigma)$. It turns out that this is a decent approximation and there is no need to average the *W*'s see using the exact f_+ distribution. Doing that, we have expanded these average transition probabilities to a second order in γ , and set the approximated *W*'s to build the corresponding master and Fokker-Planck equations, in parallel with Eq. (C2). After Fokker-Planck equation turns out to be of the same general form of (20), 576

$$\{x(1-x)[1+Gx(1-x)]P(x)\}'' - \{[Gx(1-x)(1-2x) + x(1-x)N(\gamma(1-2\overline{f}_{+}) + \gamma^{2}\{1-2x-4(1-x) + \overline{f}_{+}(1-\overline{f}_{+}) - \sigma^{2}]\}) - \theta x]P\}' = 0.$$

$$(31)$$

Solving this equation for P(x) one obtains

$$P(x) = C \frac{(1-x)^{\theta}}{x(1-x)[1+Gx(1-x)]^{\theta/2-1/\delta-\kappa}} \times \left[\frac{1-(1-2x)\sqrt{\frac{G}{4+G}}}{1+(1-2x)\sqrt{\frac{G}{4+G}}}\right]^{(\theta/2-\zeta-1/\delta+\kappa)\sqrt{G/(4+G)}}, (32)$$

where

$$\kappa = \frac{1}{\delta} [1 - 4\overline{f}_+ (1 - \overline{f}_+) + 4\sigma^2]. \tag{33}$$

577

578

Comparing (32) with Eq. (21) one realizes that in the 579 environmental-noise-controlled regime, $Gx(1-x) \gg 1$, 580

$$P_{\text{modelB}}(x) = (1-x)^{2/\delta} x^{2\kappa} P_{\text{modelA}}(x),$$
 (34)

since the value of κ is typically small, while $1/\delta$ is a large 581 factor in the interesting regime of strong stabilizing effect, the 582 species richness of model B is typically larger than the species 583

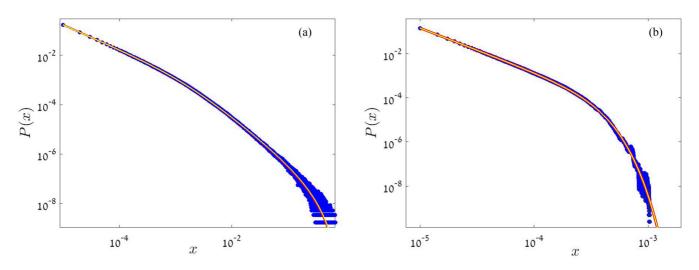

FIG. 4. The SAD, P(x) vs x, for model B. In both figures $N = 10^5$ and $\nu = 0.001$, and the results are plotted using a double logarithmic scale. The outcomes of a Monte Carlo simulation (blue circles), numeric solution for the steady state of the master equations (red line), and the analytic predictions of Eq. (32) (yellow line) are compared. In panel (a) the results are depicted for $\delta = 0.5$ and $\gamma = \sqrt{0.025}$, such that $\nu/g = 0.16$. In panel (b) $\delta = 0.1$ and $\gamma = 0.05$ so $\nu/g = 8$. The values of f_+ and σ were taken from the Monte Carlo simulations.

⁵⁸⁴ richness of model A for the same set of parameters. When δ is ⁵⁸⁵ large model A and model B have similar behavior and, if $G > \theta$ ⁵⁸⁶ one expects that the SAD will be much wider than the Fisher ⁵⁸⁷ log series; this type of behavior was observed numerically in ⁵⁸⁸ [38].

In the corresponding two-species model the stabilizing 589 effect of the noise increases the chance of rare species to 590 grow and of common species to shrink, thus stabilizing the 591 = 1/2 state. Here we see that the same stabilizing mechanism x 592 causes an increase in the species richness, i.e., it decreases 593 the mean abundance of a single species. Because $f_+ > 1/2$, 594 in the multispecies model the mean fitness of a focal species 595 is slightly smaller than the mean fitness of the community, 596 and this effect almost cancels the noise-induced growth of 597 rare species. Accordingly, the main impact of the stabilizing 598 mechanism is to limit the growth of common species. 599

The expression (32) depends on the parameters f_{+} and σ^{2} . When $N \to \infty$, these two parameters converge to $1/2 + \gamma \delta/2$ and zero, correspondingly. For finite *N* the situation is slightly more complicated. While in model A Eqs. (21) for P(x) and (24) for ζ (that depends on \overline{f}_{+}) provide a closed form, here another equation has to be used in order to determine σ^{2} in a self-consistent manner.

To do that, we begin with the calculation of the species 607 richness (SR). As we show in Appendix D, the SR distribution 608 is quite narrow with a peak at $1/\overline{x}$. Accordingly, we neglect 609 temporal and system-to-system fluctuations in the species rich-610 ness and approximate it by its peak value. Neglecting similar 611 binomial fluctuations we assume that SR/2 of the species are 612 in the plus state and SR/2 in the minus state. The chance to find 613 f_+ at a certain value ϕ is thus the chance that the abundance 614 of half of the species, which are in the plus state, sums up to ϕ 615 while the sum of the abundances of the other half (who are in 616 the minus state) is $1 - \phi$. Now we make another approximation 617 and assume that these two distributions, for the sum over the 618 plus species and the minus species, are identical, so σ^2 is not 619 affected by the difference between \overline{f}_+ and 1/2. Using the 620

central limit theorem one has

Р(

$$f_{+} = \phi) = C_{1} \exp\left(-\frac{(\phi - \overline{x} \operatorname{SR}/2)^{2}}{\operatorname{SR} \operatorname{Var}(x)}\right)$$
$$\times \exp\left(-\frac{(1 - \phi - \overline{x} \operatorname{SR}/2)^{2}}{\operatorname{SR} \operatorname{Var}(x)}\right)$$
$$= C_{1} \exp\left(-\frac{(\phi - 1/2)^{2}}{\operatorname{Var}(x)/\overline{x}}\right)$$
$$\times \exp\left(-\frac{(1 - \phi - 1/2)^{2}}{\operatorname{Var}(x)/\overline{x}}\right)$$
$$= C_{2} \exp\left(-\frac{2(\phi - 1/2)^{2}}{\operatorname{Var}(x)/\overline{x}}\right), \quad (35)$$

621

where C_1 and C_2 are normalization factors. As expected, 622 Eq. (35) suggests a slightly wrong value, 1/2, for \overline{f}_+ . Nev- 623 ertheless, it captured the leading contribution to σ^2 , 624

$$\sigma^2 \equiv \operatorname{Var}(f_+) = \frac{\operatorname{Var}(x)}{4\overline{x}}.$$
(36)

Equation (36) for σ^2 together with Eq. (32) for the distribution and Eq. (24) for \overline{f}_+ , provide a closed form from which f_{226} P(x) may be calculated iteratively by extracting \overline{x} and Var(x) f_{227} from the distribution, plugging it in the expressions for \overline{f}_+ f_{228} and σ^2 and iterating the process to convergence. This process f_{229} allows us to fit the data in Fig. 4. f_{228}

There is, of course, a numerical alternative to this procedure: 631 assuming a distribution for $P_{\pm}(x)$ one may pick numbers 632 from it until the sum reaches 1, and calculate f_+ . Iterating 633 this for many times, a direct estimation of the mean and the 634 variance of f_+ is obtained. We have verified our analytic 635 approximation using this procedure, and the deviations (for 636 the system parameters considered here) are smaller than 10%. 637

638

V. DISCUSSION

The first neutral model, the neutral theory of molecular 639 evolution, was suggested a few decades ago by Kimura [1]. 640 By incorporating spatial effects (mainland-island dynamics), 641 Hubbell [39] established the neutral model of biodiversity and 642 biogeography. In both theories the diversity of a community 643 reflects the balance between stochastic extinction and the 644 emergence of new types via mutation, speciation, or (on a local 645 community in Hubbell's model) migration. The reproduction 646 rate of all individuals is assumed to be equal at any time and the 647 only driver of abundance fluctuations is demographic noise. 648

In the immense body of literature published so far, neutral 649 models are used in three distinct contexts: first, they serve 650 as ultimate null models against which tests for selection or 651 niche-based dynamics can be applied [10,40] (though see [41]). 652 Second, these models describe the dynamics of all kinds of 653 mutations and phenotypic variations that does not affect fitness 654 (e.g., synonymous mutations). Third, even in systems like 655 tropical trees or coral reefs one may argue that the very different 656 species play, more or less, a neutral game, since the inferior 657 species are already extinct, a mechanism known as emergent 658 neutrality [31,42,43].

In this paper we have considered the simplest (and most 660 important) neutral theory, the well-mixed model of Kimura 661 which (without environmental noise) satisfies Ewens' sam-662 pling formula [44]. Under environmental variations that in-663 dependently affect the relative fitness of species, such that all 664 species still have the same time-average fitness, we provided 665 here the average (over histories and states of the environment) 666 SAD. 667

A remark about nomenclature should be added. Some will 668 argue that our model does not deserve the title "neutral" since, 669 for them, the concept of neutrality implies that all species 670 are demographically equivalent at every instant of time. For 671 example, in [45] the same phenomenon discussed here were 672 considered as part of a non-neutral model with temporal niche 673 differentiation. However, it is clear that demographic equiv-674 alence is a matter of scale. Demographic and environmental 675 stochasticity are the two extremes of the same phenomenon, 676 namely, the stochastic effects of the environment on the fitness 677 of a population: demographic noise is uncorrelated between 678 different individuals, while the "environmental stochasticity" 679 are those random variations that coherently affect an entire pop-680 ulation. For us, neutrality means symmetry between species, 681 i.e., it corresponds to the assumption that the time-average 682 fitness of all species is the same and that the dynamics is driven 683 by (various kinds of) fluctuations. 684

Previous works that dealt with this problems were focused 685 on the dynamics of a single species with fluctuating growth 686 rate, such that the time-averaged growth rate is $(-\nu)$ [31,32]. 687 These works differ from the analysis presented here in two 688 aspects: First, in our model the growth rate (when a species 689 is favored by the environment) decays with its fraction x, and 690 second (and more important) by considering the increase in 691 the number of individuals in the plus state, which manifests 692 itself in the value of $f_+ > 1/2$. This second effect leads to 693 an increased pressure on a focal species, hence the power-law 694 decay [Eq. (27)] at large values of x is characterized by an 695 exponent which is larger than the exponent predicted for a 696

two-species game. In [30] the effect of the mutations on the $_{697}$ growth rate of an existing species was neglected, and again the $_{698}$ extra pressure due to $f_+ > 1/2$ was not taken into account. $_{699}$

In some circumstances, environmental stochasticity may 700 act as a stabilizer of the community dynamics, increasing 701 the chance of a new mutant to invade and decreasing the 702 chance of a dominant species to grow. This phenomenon 703 was pointed out by Chesson and co-workers [34,46] and is 704 known in the ecological literature as the storage effect. The 705 storage effect stabilizes a coexistence state when the fitness 706 affects recruitment but death occurs at random. This is the 707 situation in our model B, which is very similar to the lottery 708 game considered by Chesson and Warner [34]; see a detailed 709 discussion in [25]. On the other hand, in model A fitness affects 710 both birth and death in an anticorrelated manner. As a result 711 there is no storage effect stabilization in that case. 712

Demographic noise and mutations were not taken into 713 account in the works of [34,46], so their models did not allow 714 for extinction (i.e., for an absorbing state) and of course one 715 cannot use them to study extinction-mutation equilibrium. Moreover, for neutral dynamics without demographic noise γ cancels out from the steady state equations so the SAD depends only on δ [25,46]: this happens because there is no 719 other scale in the problem, and leads to the paradoxical result 720 that the steady state SAD is independent of the amplitude of 721 environmental variations. When demographic stochasticity is 722 taken into account, as we did here, the parameter $G = Ng_{723}$ sets the scale of environmental noise in terms of demographic 724 stochasticity, and allows for a smooth transition between the 725 purely demographic and the environmental models. 726

In the original neutral model, with pure demographic noise 727 and a Fisher log series SAD, P(x) decays like 1/x for $x \ll$ $1/(N\nu)$ and the decay is exponential above this point. In model 729 A, the main effect of environmental stochasticity is to allow for 730 species with higher abundance; if environmental variations are 731 strong enough the exponential cutoff is replaced by a power-732 law decay as in Eq. (27). This implies that in such a system 733 both the number and the abundance of "hyperdominant" [8,47] 734 species is larger, and the overall species richness is smaller, 735 than in a system without environmental variations and the same 736 speciation rate. Recently, the heterogeneity of SADs obtained 737 in the marine biosphere was shown to be greater than expected by a purely demographic neutral model [48]—this may be an 739 indication for the effect of environmental variations. As species 740 richness reflects a speciation-extinction balance, this observa-741 tion is consistent with the results of previous works, where we 742 showed that the time to absorption shrinks when environmental 743 stochasticity turned on and there is no mechanism that allows 744 for noise induced stabilization [14,26,28]. 745

The response of model B systems to environmental fluctuations is more intricate. In a model without mutations and without demographic noise, the single species SAD peaks at 1/SR 748 [26], but this implies that such a system is vulnerable to the invasion of a new species. The remnant of this behavior is the Beta-distribution-like function that multiplies P(x) of model A to yield the SAD of model B in Eq. (34). When δ is large, model A and B behave similarly. However when δ is small and the stabilizing effect is strong, the SAD has a strong cutoff at $x \sim \delta/2$ and the species richness increases substantially with respect to model A with the same parameters. Moreover, when 776

⁷⁵⁷ $\delta < 2/\theta$ the species richness of model B will be even larger ⁷⁵⁸ than the SR of the purely demographic neutral model that has ⁷⁵⁹ a cutoff at $x = 1/\theta$, as already demonstrated numerically in ⁷⁶⁰ Fig. 5 of [26].

There are some limitations to our analysis: first, we assumed 761 that the size of the community N is large, and that the number 762 of species in the steady state is much larger than 2 (otherwise 763 the mean-field approach failed, in particular the neglect of the 764 time dependence of f_+ becomes problematic). Moreover, our 765 approximations fail when δ becomes extremely large ($f_+ \rightarrow$ 766 1), since in such a case the system reduces to a neutral model 767 for all the plus state species, while the minus species simply go 768 extinct. These limitations, of course, have nothing to do with 769 the practical applications of the neutral model to empirical 770 dynamics like those considered in [17,21]. We believe that 771 the theory presented here, when applied to experiments and 772 field data in population genetics and community ecology, 773 774 may suggest many insights into the processes that govern the 775 composition of populations and communities.

APPENDIX A: FROM MASTER EQUATION TO FOKKER-PLANCK EQUATION: CONTINUUM APPROXIMATION AND BOUNDARY CONDITIONS

The Fokker-Planck equations studied through this paper are 782 obtained as a continuum approximation of an exact master 783 equation. The justification for this procedure, and its limita-784 tions, were discussed in detail in [49]; in this appendix we 785 provide a few comments that illustrate the method used here, 786 with a particular emphasis on the boundary conditions. We 787 stick to a simple system that allows us to demonstrate the 788 problems and their solutions while keeping the algebra and 789 calculus relatively straightforward. 790

To begin, let us write down the master equation for a generic system with nearest neighbors transitions where the number of individuals is between 1 and *N*. If $W_{n\pm 1\rightarrow n}$ and $W_{n\rightarrow n}$ are the probabilities to jump into the state with *n* individuals during one elementary step (after each elementary step, time is incremented by 1/N), the master equation takes the form

$$P_{1}^{t+1/N} = W_{1\to1}P_{1}^{t} + W_{2\to1}P_{2}^{t},$$

$$P_{n}^{t+1/N} = W_{n\to n}P_{n}^{t} + W_{n+1\to n}P_{n+1}^{t} + W_{n-1\to n}P_{n-1}^{t},$$

$$1 < n < N,$$

$$P_{N}^{t+1/N} = W_{N\to N}P_{N}^{t} + W_{N-1\to N}P_{N-1}^{t}.$$
(A1)

In the steady state, $P_n^{t+1/N} = P_n^t$ for all *n*'s. In such a case 797 the set of equations (A1) appears to provide N equations 798 for the N unknown variables P_n . However, conservation of 799 800 probability implies that the corresponding Markov matrix is singular, i.e., it admits a nontrivial eigenstate with zero eigen-801 value. The missing constraint is supplied by the normalization 802 condition $\sum P_n = 1$, and with this condition the solution is 803 fully specified. This example may be generalized to include 804 environmental noise, long-range hopping, and so on. 805

PHYSICAL REVIEW E 00, 002400 (2018)

Now let us discuss the transition to the continuum. The simplest way to make this approximation is to consider both P and W as functions of x = n/N, and to expand quantities like $P_{n+1} \rightarrow P(x + 1/N)$ to second order in 1/N. If it is possible some to use this procedure for any value of n (and this is not the stock) the equations for P_1 and P_N , which are not still in the general form of all other equations, supply a no-flux structure (Robin) boundary condition at x = 0 and x = 1. As before, structure the satisfaction of one boundary condition structure is not specified structure the satisfaction of the other one. The structure the structure the structure to the structure of the other one. The structure the structure the structure to the str

To examine the transition to continuum more closely, let us specify the transition probabilities. As an example we take a two-species neutral model with pure demographic noise and "reflecting" boundary conditions. At each step one individual is chosen at random to die and is replaced by an offspring of another, randomly chosen, individual. However, a singleton (the last individual that belongs to a certain species) cannot die. The corresponding transition probabilities are

$$W_{n-1\to n} = \frac{(n-1)(N-n+1)}{N(N-1)}, \quad 2 \le n \le N-1,$$

$$W_{n+1\to n} = \frac{(n+1)(N-n-1)}{N(N-1)}, \quad 1 \le n \le N-2,$$

$$W_{n\to n} = \left(1 - \frac{2n(N-n)}{N(N-1)}\right), \quad 2 \le n \le N-2,$$

$$W_{1\to 1} = (1 - W_{1\to 2}), \quad W_{N-1\to N-1} = (1 - W_{N-1\to N-2}).$$

(A2)

Interestingly, for this model the steady state of the master equation (A1) has a simple form,

$$P_n = \frac{A}{n(N-n)},\tag{A3}$$

that satisfies both the master equation and the boundary see condition. *A* is determined by the normalization condition.

Plugging the transition probabilities in Eq. (A2) into ⁸³¹ Eq. (A1), the continuum equation is obtained by the set ⁸³² of replacements n = xN, $P_n \rightarrow P(x)$, and $P_{n\pm 1} \rightarrow P(x) \pm$ ⁸³³ $P'(x)/N + P''(x)/2N^2$. The middle equation of (A1) is translated into ⁸³⁵

$$\frac{dP(x,t)}{dt} = \frac{1}{N^2} \frac{\partial^2}{\partial x^2} [x(1-x)P(x)], \qquad (A4)$$

and the steady state solution satisfies $\dot{P} = 0$, namely,

$$\frac{1}{N^2} \frac{\partial^2}{\partial x^2} [x(1-x)P(x)] = 0.$$
 (A5)

The steady state solution of Eq. (A4) has the general form

$$P(x) = \frac{A + Bx}{x(1 - x)}.$$
 (A6)

836

As explained above, one of the free constants A and B should ⁸³⁸ be determined by (one of) the boundary conditions, while ⁸³⁹ the other allows for normalization. Comparing (A6) and (A3) one realizes that B = 0 should be the correct answer, but the derivation of this result from the boundary conditions of the continuum differential equation is not trivial.

The problem (that has already been discussed in [49]) 844 is that the continuum approximation itself may break close 845 to x = 0 and x = 1. For example, in our case $P_1 \approx 2P_2$. 846 Deriving the boundary condition from a continuum approxima-847 tion, P(2/N) = P(1/N) + P'(1/N)/N, one finds P'(1/N) =848 NP(1/N)/2, but this is incompatible with B = 0 in Eq. (A6) 849 [B = 0 implies P'(1/N) = NP(1/N), without the factor 2].850 This happens because the derivation of the boundary condition 851 assumes that P_n is smooth so the first derivative may be 852 extracted from the difference between P_1 and P_2 , but since 853 the actual difference is a factor of 2, the approximation fails 854 and supplies the wrong boundary condition. 855

A way to solve this problem is to define another variable that will be smooth at the boundaries. For example, 857 the quantity Y = x(1 - x)P undergoes a simple diffusion 858 process so Eq. (A4) implies that at equilibrium Y = A + Bx, 859 hence Y'(x) = B. The boundary condition is translated to 860 Y(1/N) = Y(2/N), i.e., Y'(1/N) = 0, and this implies B = 0861 as requested. However, we are not familiar with a method that 862 will allow us to produce a corresponding variable in more 863 complicated scenarios. 864

The generic method, suggested in [49], is to solve the difference (master) equation exactly at the vicinity of the boundary, and then to match this expression to the solution of the differential (Fokker-Planck) equation in the bulk using the asymptotic matching technique. However, for the problems at hand this is a very complicated procedure and we have tried to avoid it. Returning to the steady state equation (A5), one notices ⁸⁷² that the constant *B* is related to the first integration, i.e., ⁸⁷³ $[x(1-x)P(x)]'/N^2 = B$, so taking B = 0 implies that after ⁸⁷⁴ the first integration the remaining equation is still homogenous. ⁸⁷⁵ This is not an incident: it happens since the original problem ⁸⁷⁶ satisfies *detailed balance*: $P_nW_{n\to n+1} = P_{n+1}W_{n+1\to n}$, i.e., the ⁸⁷⁷ probability flux between each pair of neighboring states is zero. ⁸⁷⁸

The detailed balance condition must hold in the steady state of Markov chains, by induction from P_1 . Accordingly, in 880 any one-dimensional Fokker-Planck equation with the general 881 form [A(x)P(x)]'' + [B(x)P(x)]' = 0 and reflecting boundary 882 conditions one should omit the first integration constant. In the next appendixes we consider systems that may, in principle, 884 allow for loops, but we map them to a one-dimensional system; 885 so as long as our approximation holds, the detailed balance 886 condition must be satisfied. As N increases this approximation 887 becomes better and better, since the relative width of the boundary zone approaches zero. Accordingly, through this paper we 889 implement this detailed balance approximation (namely, we drop the first integration constant). The fits of our results to the numerical solutions of the master equations indicate that this 892 is indeed a decent approximation. 893

APPENDIX B: FOKKER-PLANCK EQUATION FOR THE TWO-SPECIES MODEL WITH ONE-WAY MUTATIONS

In this appendix we derive the effective one-dimensional ⁸⁹⁶ Fokker-Planck equation for a model with two species (types) A ⁸⁹⁷ and B, with both demographic and environmental stochasticity, ⁸⁹⁸ and with one-sided mutations (an offspring of A may mutate ⁸⁹⁹ into B, but an offspring of B is always a B), as described in ⁹⁰⁰ Sec. III of the main text. ⁹⁰¹

To begin, let us introduce two quantities, $P_{n,+}^t$, the chance of finding the system with *n* A-type individuals in the $(+\gamma)$ state ⁹⁰² at time *t*, and $P_{n,-}^t$, the chance of finding the system in the $(-\gamma)$ state with *n* A-type individuals. The time evolution (time is ⁹⁰³ incremented by 1/N after each elementary step) of $P_{n,\pm}$ is governed by the two coupled master equations: ⁹⁰⁴

$$P_{n,+}^{t+1/N} = P_{n+1,+}^{t} W_{n+1\to n}^{++} + P_{n-1,+}^{t} W_{n-1\to n}^{++} + P_{n,+}^{t} W_{n\to n}^{++} + P_{n-1,-}^{t} W_{n-1\to n}^{-+} + P_{n+1,-}^{t} W_{n+1\to n}^{-+} + P_{n,-}^{t} W_{n\to n}^{-+},$$

$$P_{n,-}^{t+1/N} = P_{n+1,-}^{t} W_{n+1\to n}^{--} + P_{n-1,-}^{t} W_{n-1\to n}^{--} + P_{n-1,+}^{t} W_{n-1\to n}^{+-} + P_{n+1,+}^{t} W_{n+1\to n}^{+-} + P_{n,+}^{t} W_{n\to n}^{+-},$$
(B1)

where $W_{n-1 \rightarrow n}^{++}$, for example, is the probability to increase the *A*-type population by 1 (from n - 1 to *n* individuals) while staying in the plus environment, and $W_{n-1 \rightarrow n}^{+-}$ is the chance that the environment switches from plus to minus and then the *A*-type population grows.

If the abundance of species A is n, the chance of an interspecific duel for two randomly picked individuals is $F_n = 2n(N - M)/N^2$ when $N \gg 1$. Using this notation we can write the transition probabilities as

$$\begin{split} W_{n+1\to n}^{++} &= \left(1 - \frac{1}{\delta N}\right) \left[(1 - \nu) F_{n+1} \left(\frac{1}{2} - \frac{\gamma}{4}\right) + \nu \frac{n+1}{N} \right], & W_{n-1\to n}^{++} &= \left(1 - \frac{1}{\delta N}\right) \left[(1 - \nu) F_{n-1} \left(\frac{1}{2} + \frac{\gamma}{4}\right) \right], \\ W_{n+1\to n}^{--} &= \left(1 - \frac{1}{\delta N}\right) \left[(1 - \nu) F_{n+1} \left(\frac{1}{2} + \frac{\gamma}{4}\right) + \nu \frac{n+1}{N} \right], & W_{n-1\to n}^{--} &= \left(1 - \frac{1}{\delta N}\right) \left[(1 - \nu) F_{n-1} \left(\frac{1}{2} - \frac{\gamma}{4}\right) \right], \\ W_{n+1\to n}^{-+} &= \frac{1}{\delta N} \left[(1 - \nu) F_{n+1} \left(\frac{1}{2} - \frac{\gamma}{4}\right) + \nu \frac{n+1}{N} \right], & W_{n-1\to n}^{-+} &= \frac{1}{\delta N} \left[(1 - \nu) F_{n-1} \left(\frac{1}{2} + \frac{\gamma}{4}\right) \right], \end{split}$$
(B2)
$$W_{n+1\to n}^{+-} &= \frac{1}{\delta N} \left[(1 - \nu) F_{n+1} \left(\frac{1}{2} + \frac{\gamma}{4}\right) + \nu \frac{n+1}{N} \right], & W_{n-1\to n}^{+-} &= \frac{1}{\delta N} \left[(1 - \nu) F_{n-1} \left(\frac{1}{2} - \frac{\gamma}{4}\right) \right], \\ W_{n+1\to n}^{++} &= W_{n\to n}^{--} &= \left(1 - \frac{1}{\delta N}\right) \left[(1 - \nu) (1 - F_n) + \nu \left(1 - \frac{n}{N}\right) \right], & W_{n\to n}^{+-} &= W_{n\to n}^{-+} &= \frac{1}{\delta N} \left[(1 - \nu) (1 - F_n) + \nu \left(1 - \frac{n}{N}\right) \right]. \end{split}$$

THEORY OF TIME-AVERAGED NEUTRAL DYNAMICS WITH ...

As explained, our system admits a single absorbing state at n = 0 and the dynamics inevitably leads to the extinction of the *A* species, so we have to assume that, very rarely (on timescales that are much larger than the extinction time) a new *A* individual arrives and the game is played over and over again. If our interest is in the chance of *A* to have abundance *n* conditioned on its existence in the system, we can merge together all the colonization-extinction periods. Colonizations are random in time, so the chance of a colonization during each state period is 1/2. This is equivalent to the use of the master equation (B1) only for $n \ge 2$, while for n = 1 the boundary equations are

$$P_{1,+}^{t+1/N} = P_{2,+}^{t} W_{2\to1}^{++} + P_{2,-}^{t} W_{2\to1}^{-+} + P_{1,+}^{t} W_{1\to1}^{++} + P_{1,-}^{t} W_{1\to1}^{-+} + \frac{1}{2} ([W_{1\to0}^{++} + W_{1\to0}^{+-}] P_{1,+}^{t} + [W_{1\to0}^{--} + W_{1\to0}^{-+}] P_{1,-}^{t}),$$

$$P_{1,-}^{t+1/N} = P_{2,-}^{t} W_{2\to1}^{--} + P_{2,+}^{t} W_{2\to1}^{+-} + P_{1,-}^{t} W_{1\to1}^{--} + P_{1,+}^{t} W_{1\to1}^{+-} + \frac{1}{2} ([W_{1\to0}^{++} + W_{1\to0}^{+-}] P_{1,+}^{t} + [W_{1\to0}^{--} + W_{1\to0}^{-+}] P_{1,-}^{t}).$$
(B3)

 $_{916}$ Equations (B1)–(B3) define a linear equation

$$P^{t+1/N} = \mathcal{M}P^t,\tag{B4}$$

⁹¹⁷ where P^t is a 2N vector ($P_i = P_{n=i,+}$ for $i \le N$ and $P_{n=i-N,-}$ for $N < i \le 2N$) and \mathcal{M} is a 2N × 2N Markov matrix. The ⁹¹⁸ steady state is the eigenvector of \mathcal{M} with the (highest) eigenvalue $\lambda = 1$. To obtain a solution for this steady state given a set of ⁹¹⁹ parameters that determine the elements of \mathcal{M} we have solved numerically for this eigenvalue. As discussed in Appendix A, the ⁹²⁰ overall scale of the steady state P_n 's is determined by the normalization condition.

Now we would like to develop a Fokker-Planck differential equation for this steady state distribution. Defining P_n^+ (P_n^-) as the chances to find the system with *n* individuals in the plus (minus) state in a period between colonization and extinction, Eq. (B3) takes the form

$$P_{n}^{+} = P_{n+1}^{+} W_{n+1 \to n}^{++} + P_{n-1}^{+} W_{n-1 \to n}^{++} + P_{n}^{+} W_{n \to n}^{++} + P_{n-1}^{-} W_{n-1 \to n}^{-+} + P_{n+1}^{-} W_{n+1 \to n}^{-+} + P_{n}^{-} W_{n \to n}^{-+},$$

$$P_{n}^{-} = P_{n+1}^{-} W_{n+1 \to n}^{--} + P_{n-1}^{-} W_{n-1 \to n}^{--} + P_{n}^{+} W_{n-1 \to n}^{+-} + P_{n+1}^{+} W_{n+1 \to n}^{+-} + P_{n}^{+} W_{n \to n}^{+-}.$$
(B5)

Plugging (B2) into (B5) and using the definition $q \equiv 1/2 + \gamma/4$ (this is the parameter q_A , introduced in Sec. III, in the plus state):

$$P_{n}^{+} = \left(1 - \frac{1}{N\delta}\right) \left\{ (1 - \nu)(qF_{n-1}P_{n-1}^{+} + (1 - q)F_{n+1}P_{n+1}^{+} + (1 - F_{n})P_{n}^{+}) + \nu\left(\frac{n+1}{N}P_{n+1}^{+} + \frac{N-n}{N}P_{n}^{+}\right) \right\} \\ + \frac{1}{N\delta} \left\{ (1 - \nu)((1 - q)F_{n-1}P_{n-1}^{-} + qF_{n+1}P_{n+1}^{-} + (1 - F_{n})P_{n}^{-}) + \nu\left(\frac{n+1}{N}P_{n+1}^{-} + \frac{N-n}{N}P_{n}^{-}\right) \right\}, \\ P_{n}^{-} = \left(1 - \frac{1}{N\delta}\right) \left\{ (1 - \nu)((1 - q)F_{n-1}P_{n-1}^{-} + qF_{n+1}P_{n+1}^{-} + (1 - F_{n})P_{n}^{-}) + \nu\left(\frac{n+1}{N}P_{n+1}^{-} + \frac{N-n}{N}P_{n}^{-}\right) \right\} \\ + \frac{1}{N\delta} \left\{ (1 - \nu)(qF_{n-1}P_{n-1}^{+} + (1 - q)F_{n+1}P_{n+1}^{+} + (1 - F_{n})P_{n}^{+}) + \nu\left(\frac{n+1}{N}P_{n+1}^{+} + \frac{N-n}{N}P_{n}^{+}\right) \right\}.$$
(B6)

These two coupled difference equations for P^+ and P^- may be translated to another pair of coupled difference equations for their sum (which is the chance to be at *n*, no matter what the weather) and their difference,

$$P_n \equiv P_n^+ + P_n^-, \quad \Delta_n \equiv P_n^+ - P_n^-.$$
 (B7)

Defining $x \equiv n/N$ one may switch to the continuum limit, with $P_n \to P(x)$ and $P_{n\pm 1} \to P(x \pm 1/N)$. Expanding to second order in 1/N, the emerging couple of steady state differential equations is

$$(1-\nu)\left\{\frac{1}{N}[x(1-x)\Delta]'' - \gamma[x(1-x)P]'\right\} + \nu[x\Delta]' = \frac{2\Delta}{\delta(1-\frac{2}{\delta N})},$$

$$(1-\nu)\left\{\frac{1}{N}[x(1-x)P]'' - \gamma[x(1-x)\Delta]'\right\} + \nu[xP]' = 0.$$
(B8)

In what follows (and in the main text) we neglect the difference between $1 - \nu$ and 1, since in the relevant parameter regime ν is very small compared to 1 (otherwise one may similar process where the rate of duels is 1 and the rate of mutations is ν , this $(1 - \nu)$ factor disappears). Moreover, since we are interested in the large N, fixed δ limit, $2/(\delta N) \ll 1$. Dominant balance analysis (see discussion below) reveals $_{937}$ that, for reasonably large *N*, the first and the third term in the $_{938}$ upper equation of (B8) are negligible. Accordingly, $_{939}$

$$\Delta = \frac{\gamma \delta}{2} [x(1-x)P]'. \tag{B9}$$

⁹⁴⁰ When this expression is plugged into the second equation one ⁹⁴¹ obtains an autonomous equation for P,

$$\begin{bmatrix} x(1-x)\left(\frac{1}{N} + gx(1-x)\right)P \end{bmatrix}'' -\{[gx(1-x)(1-2x) - vx]P\}' = 0, \quad (B10)$$

where $g \equiv \delta \gamma^2/2$ is the strength of the environmental stochasticity. This equation and its solution for different parameter regimes are discussed in Sec. III of the main text.

Our dominant balance analysis was based on numerical
observations (solving numerically the Fokker-Planck equation
and comparing the magnitude of different terms) but we can
provide a few arguments for its self-consistency.

⁹⁴⁹ First, it is clear that in the demographic regime (i.e., $Gx \ll$ ⁹⁵⁰ 1) environmental fluctuations are negligible and the Δ terms ⁹⁵¹ are irrelevant, so the upper equation in (B8) plays no role. By ⁹⁵² the same token, if the *P* term in the upper equation is negligible ⁹⁵³ in the large *N* limit the solution is $\Delta = 0$ and the effect of ⁹⁵⁴ environmental stochasticity disappears, so this term should be ⁹⁵⁵ dominant when environmental variations are important.

Let us define $Y(x) \equiv x(1-x)P$, so Eq. (B9) implies that $\Delta = (\gamma \delta/2)Y'$. Clearly, as long as (B10) holds,

$$Y(x) = -\frac{1-x}{\nu} \left(\frac{1}{N} + gx(1-x)\right) Y'(x),$$
 (B11)

⁹⁵⁶ and the dominant balance argument is consistent if, as $N \rightarrow$ ⁹⁵⁹ ∞ , the two conditions,

$$\nu x \Delta \ll \gamma Y, \quad \frac{[x(1-x)\Delta]'}{N} \ll \gamma Y$$
 (B12)

960 OI

$$\frac{\delta v^2 x}{2} Y' \ll (1-x) \left(\frac{1}{N} + gx(1-x)\right) Y',$$

$$\frac{\delta v}{2N} [x(1-x)Y']' \ll (1-x) \left(\frac{1}{N} + gx(1-x)\right) Y' \quad (B13)$$

961 are satisfied.

2

When $1/N \ll gx(1-x)$ the left condition is translated 962 to $x \ll 1 - \nu/\gamma$. On the other hand, if at large N the third 963 term balances the second, $\nu x \Delta \sim \gamma Y$, one may plug it into 964 the $\gamma [x(1-x)\Delta]'$ in the lower equation of (B8) to find that 965 this term is negligible with respect to the third one if x > 1 - 1966 ν/γ . Accordingly, in the regime where our dominant balance 967 argument is wrong, environmental stochasticity is negligible. 968 Similarly, since the maximum value of Y''/Y' is θ , the right 969 condition in (B13) holds when $x \ll 1 - \nu^2/\gamma^2$, but if one 970 assumes that the dominant balance is $\frac{[x(1-x)\Delta]'}{N} \sim \gamma Y$ and plug 971 it into the lower equation of (B8), the result is $Y \sim \exp(-\theta x)$ 972 and the effect of environmental noise vanishes for $\gamma^2 < \nu^2$, so 973 we are back in the demographic regime. 974

975 APPENDIX C: A FOKKER-PLANCK EQUATION FOR 976 THE MULTISPECIES MODEL

Unlike the two-species game studied in Appendix B, here we consider the dynamics of a focal species in a multispecies environment. In a duel, an individual of the focal species may encounter an enemy with the same fitness (a neutral enemy), superior enemy (if the focal species is in the minus state), or inferior enemy (if it is in the plus state). As explained in the main text, we assume that the fraction of individuals in the plus state is fixed and equal to f_+ . Accordingly, Eq. (B1) still holds but the transition probabilities depend on the chance to find a neutral, superior, or inferior enemy. If $\nu = 0$ these probabilities are

$$W_{n\pm1\to n}^{++} = \left(1 - \frac{1}{\delta N}\right) F_{n\pm1} \left[\frac{f_{+}}{2} + (1 - f_{+})\left(\frac{1}{2} \mp \frac{\gamma}{4}\right)\right],$$

$$W_{n\pm1\to n}^{--} = \left(1 - \frac{1}{\delta N}\right) F_{n\pm1} \left[\frac{1 - f_{+}}{2} + f_{+}\left(\frac{1}{2} \pm \frac{\gamma}{4}\right)\right],$$

$$W_{n\pm1\to n}^{+-} = \frac{1}{\delta N} F_{n\pm1} \left[\frac{1 - f_{+}}{2} + f_{+}\left(\frac{1}{2} \pm \frac{\gamma}{4}\right)\right],$$

$$W_{n\pm1\to n}^{-+} = \frac{1}{\delta N} F_{n\pm1} \left[\frac{f_{+}}{2} + (1 - f_{+})\left(\frac{1}{2} \mp \frac{\gamma}{4}\right)\right],$$

$$W_{n\to n}^{++} = W_{n\to n}^{--} = \left(1 - \frac{1}{\delta N}\right)(1 - F_{n}),$$

$$W_{n\to n}^{+-} = W_{n\to n}^{-+} = \frac{1}{\delta N}(1 - F_{n}).$$
(C1)

As in Eqs. (B2), when $\nu \neq 0$, each of these terms is multiplied by $(1 - \nu)$, the quantity $\nu(n + 1)/N$ is added to all the $W_{n+1 \rightarrow n}$ substituting terms, and the quantity $\nu(1 - n/N)$ is added to all the $W_{n \rightarrow n}$ substituting terms.

Using the same boundary conditions (B3), we can solve $_{992}$ numerically for the steady state of the linear equation (B4) $_{993}$ using an iterative procedure: starting from an initial value of $_{994}$ f_+ we solve for the steady state, calculate (for this steady state) $_{995}$ the new value of f_+ using the discrete version of Eq. (22), and $_{996}$ iterate this process until convergence. $_{997}$

Expanding Eq. (B5), using the new Ws, we obtain

$$(1-\nu)\left\{\frac{1}{N}[x(1-x)\Delta]'' - \gamma[x(1-x)(P+(1-2f_{+})\Delta]'\right\} + \nu[x\Delta]' = \frac{2\Delta}{\delta(1-\frac{2}{\delta N})},$$

$$(1-\nu)\left\{\frac{1}{N}[x(1-x)P]'' - \gamma[x(1-x)(\Delta+(1-2f_{+})P]'\right\} + \nu[xP]' = 0.$$
 (C2)

Using the dominant balance argument and the approximations 999 that we presented in the appendixes above, the upper equation 1000 of (C2) becomes 1001

$$\Delta = -\frac{\gamma\delta}{2}[x(1-x)P]'.$$
 (C3)

998

1004

Plugging this expression for Δ into the lower equation one 1002 finds the effective Fokker-Planck equation for P(x), 1003

$$\left[x(1-x)\left(\frac{1}{N}+gx(1-x)\right)P\right]'' - (\{x(1-x)[g(1-2x) + \gamma(1-2f_+)] - \nu x\}P)' = 0,$$
(C4)

which is Eq. (20) of the main text.

THEORY OF TIME-AVERAGED NEUTRAL DYNAMICS WITH ...

1005 APPENDIX D: THE SPECIES RICHNESS AND 1006 ITS DISTRIBUTION

This paper is focused on the species abundance distribution (SAD). In this appendix we would like to provide an expression for the overall species richness in the community given the SAD. To do that we implement standard tools which are relevant to any SAD, not only to those considered above.

We start from P(x), the chance that a randomly chosen species has abundance x. Picking numbers at random from this distribution until their sum exceeds 1, a possible instantaneous realization of the composition of the system is obtained. Defining the random variable

$$z_k = \sum_{j=1}^k x_j, \tag{D1}$$

1017 one realizes that the cumulative distribution function (CDF)1018 for the species richness is

$$P(SR < k) = 1 - P(z_k < 1).$$

The central limit theorem suggests that z_k is distributed like a 1019 Gaussian random variable with mean $k\overline{x}$ and variance kVar(x). 1020 Accordingly, 1021

$$P(SR < k) = 1 - \frac{1}{\sqrt{\pi}} \int_{a}^{b} dy \ e^{-y^{2}},$$
 (D3)

where $y \equiv (z_k - k\overline{x})/\sqrt{2k \operatorname{Var}(x)}$, $a = y(z_k = 0)$, and b = 1022 $y(z_k = 1)$. The distribution function for the species richness 1023 is the derivative of this CDF, and if $2\operatorname{Var}(x) \ll \overline{x}$ (which is the 1024 common case), 1025

$$P(SR = k) = \frac{(\bar{x}k + 1)e^{-(\bar{x}k - 1)^2/2Var(x)k}}{2\sqrt{2\pi Var(x)k^{3/2}}}.$$
 (D4)

Equation (D4) is a slightly skewed Gaussian that peaks at $k = \frac{1026}{1/\overline{x}}$.
